SCOTTYRANK.JL: AN IMPLEMENTATION OF PAGERANK & HITS

SIYUAN CHEN AND MICHAEL ZHOU

ABSTRACT. We present ScottyRank.jl, a Julia implementation of the PageRank algorithm and one of its successors, the HITS algorithm. Famously used by Google, PageRank, as well as its variations, models a network of interest (such as the Internet) as a simple directed graph and produces relative rankings of the vertices that roughly translate to the vertices' levels of relevance and importance.

In this paper, we first introduced the mathematical background for the two algorithms. We then outlined the core algorithmic insights of both PageRank and HITS and expressed them in matrix form. Using code segments, we presented our implementation of the two algorithms. Finally, we ran the two algorithms on the Wikipedia PageRank network and analyzed the outputs. [6] We included the source code in the Appendix.

1. Background

1.1. Linear Algebra.

1.1.1. Definitions. Positive matrices are defined as matrices with positive entries.

Markov matrices are defined as square matrices with nonnegative entries and column sum 1 across all of its columns. Note that for a $n \times n$ matrix M, the latter condition is equivalent to $M^T \vec{1} = \vec{1}$, where $\vec{1} \in \mathbb{R}^n$ has all ones as components.

Positive Markov matrices are defined as, well, positive Markov matrices.

1.1.2. Facts. (Perron-Frobenius theorem) Let A be a positive square matrix. Let λ_1 be A's maximum eigenvalue in terms of absolute values. Then λ_1 is positive and has algebraic (and subsequently geometric) multiplicity 1. [7]

Let M be a Markov matrix. Let λ_1 be M's maximum eigenvalue in terms of absolute values. Then $\lambda_1 = 1$. [4]

Let M' be a positive Markov matrix. Let λ_1 be M''s maximum eigenvalue in terms of absolute values. Then $\lambda_1 = 1$ and has algebraic (and subsequently geometric) multiplicity 1.

1.1.3. Usage. Let M be a $n \times n$ Markov matrix. Then M specifies a dicrete memoryless transition process between n states, namely the process where

$$(\forall (t, i, j) \in \mathbb{N} \times [n] \times [n]) [Pr(\text{state } i \text{ at time } t + 1 \mid \text{state } j \text{ at time } t) = M_{ij}].$$

Let $\vec{v} \in \mathbb{R}^n$ such that \vec{v} has nonnegative components and $\vec{v}^T \vec{1} = 1$ (a stochastic vector). Then \vec{v} specifies an (initial) discrete probability distribution over the n states, namely the distribution where

$$(\forall i \in [n])[\Pr(\text{state } i \text{ at time } 0) = \vec{v_i}].$$

Then the probability distribution over the n states after t steps of the transition process specified by M is precisely $M^t \vec{v}$, or equivalently

$$(\forall (t,i) \in \mathbb{N} \times [n]) \left[\text{Pr}(\text{state } i \text{ at time } t) = \left(M^t \vec{v} \right)_i \right].$$

1.2. Graph Theory.

1.2.1. *Definitions*. A simple directed graph is defined as an unweighted directed graph without self-referential edges or multiple edges between the same origin destination pair.

For a simple directed graph with n vertices, the adjacency matrix \mathcal{A} is defined to be the $n \times n$ matrix where

$$(\forall (i,j) \in [n] \times [n]) \left(A_{ij} = \begin{cases} 1 & \text{there is an edge to } i \text{ from } j \\ 0 & \text{otherwise} \end{cases} \right).$$

1.2.2. Facts. For a simple directed graph with n vertices and its adjacency matrix A,

$$(\forall j \in [n])$$
 [number of outgoing neighbors from vertex $j = \text{out}(j) = (\mathcal{A}_{*j})^T \vec{1}$]
 $(\forall i \in [n])$ [number of incoming neighbors to vertex $i = \text{in}(i) = (\mathcal{A}_{i*})^T \vec{1}$].

2. Algorithms

2.1. **The Network Model.** Both algorithms, PageRank and HITS, model the network of interest as a simple directed graph with websites as vertices and links as edges. This implies that there will be no self-referential links, no duplicate links between the same origin and destination pair, and no priority difference between links.

2.2. PageRank.

- 2.2.1. The random walk. PageRank models the behavior of a typical web surfer as a damped random walk. [6]
 - (1) The surfer starts out by visiting a random site out of all sites with equal probability.
 - (2) At every step, the surfer has a probability λ of continuing surfing and a complementary 1λ probability of losing interest, for a predetermined λ .
 - (a) If the surfer continues ...
 - (i) ... and there are links exiting the current site, the surfer clicks on a random link (and visits the site it points to) out of those links with equal probability.
 - (ii) ... and there aren't any links exiting the current site, the surfer simply visits a random site out of all other sites with equal probability.
 - (b) If the surfer loses interest, they simply visits a random site out of all sites with equal probability.

To best model a typical surfer's probability of continuing surfing, λ , also known as the damping factor, is empirically determined to be around 0.85.

2.2.2. Matrix representation. Let n be the number of websites in the network of interest. Let A be the adjacency matrix for the network of interest. Let $\langle \vec{v}_t \rangle_{t \in \mathbb{N}}$ be the probability distributions describing the website the surfer is visiting at time t. Let M be the transition matrix for the random walk process.

Then $\vec{v}_0 = \vec{1}/n$, M is the $n \times n$ matrix where

$$(\forall (i,j) \in [n] \times [n]) \begin{bmatrix} M_{ij} = \begin{cases} \frac{\lambda}{\operatorname{out}(j)} + \frac{1-\lambda}{n} & \mathcal{A}_{ij} = 1\\ \frac{1-\lambda}{n} & \mathcal{A}_{ij} = 0 \land \operatorname{out}(j) > 0\\ \frac{\lambda}{n-1} + \frac{1-\lambda}{n} & i \neq j \land \operatorname{out}(j) = 0\\ \frac{1-\lambda}{n} & i = j \land \operatorname{out}(j) = 0 \end{cases},$$

and

$$(\forall t \in \mathbb{N}) \left(\vec{v_t} = M^t \vec{v_0} \right).$$

Note that in this case M is a positive Markov matrix, assuming reasonable λ .

2.2.3. Definition. The PageRank score for a given website in the network of interest is defined as the probabilty of a typical surfer visiting that website after an indefinitely long damped random walk. In matrix form,

$$(\forall i \in [n]) \left[\text{PageRank}(i) = \lim_{t \to \infty} (\vec{v_t})_i = \lim_{t \to \infty} (M^t \vec{v_0})_i \right].$$

Note that the limits exist: convergence is guaranteed as M has a unique maximal eigenvalue of 1 and thus an steady attracting state.

2.3. **HITS.**

2.3.1. Authorities and hubs. Due to PageRank's algorithmic design, a given website's PageRank score determined mostly by the scores of its incoming neighbors. Consequently, PageRank tends to underestimate the importance of websites similar to "web directories", i.e., those with few significant incoming neighbors yet many significant outgoing neighbors.

To address this issue, HITS (Hyperlink-Induced Topic Search) introduces Authority and Hub scores, which measure a given website's tendencies to be refered to by others and to refer to others, respectively. Note that the two metrics are not "mutually exclusive"; a website like Wikipedia can have both a high Authority score and a high Hub score.

Specifically, Authority and Hub scores are recursively defined: a website's Authority score is determined by the Hub scores of its incoming neighbors and its Hub score is determined by the Authority scores of its outgoing neighbors. [5]

2.3.2. Matrix representation. Let n be the number of websites in the network of interest. Let $\langle \vec{a}_t \rangle_{t \in \mathbb{N}}$ and $\langle \vec{h}_t \rangle_{t \in \mathbb{N}}$ be the (pre-normalization) Authority and Hub scores for the n websites at time t.

Then $\vec{a}_0 = \vec{h}_0 = \vec{1}$ and

$$(\forall t \in \mathbb{N}) \left[\left(\vec{a}_{t+1}, \vec{h}_{t+1} \right) = \left(\mathcal{A} \vec{h}_t, \mathcal{A}^T \vec{a}_t \right) \right].$$

2.3.3. Definition. The Authority and Hub scores for a given website in the network of interest is defined as the respective scores after indefinitely many iterations. In matrix form,

$$(\forall i \in [n]) \left[(\text{Authority}(i), \text{Hub}(i)) = \lim_{t \to \infty} \left((\vec{a}_t)_i, (\vec{h}_t)_i \right) \right].$$

To guarantee convergence, the Authority and Hub scores are normalized. Our implementation performs normalization after every iteration. This means

$$(\forall t \in \mathbb{N}) \left[\|(\vec{a}_t)'\| = \|(\vec{h}_t)'\| = 1 \right]$$

where

$$(\forall t \in \mathbb{N}) \left[(\vec{a}_t)' = \frac{\vec{a}_t}{\|\vec{a}_t\|} \wedge (\vec{h}_t)' = \frac{\vec{h}_t}{\|\vec{h}_t\|} \right].$$

3. Implementation

3.1. **Structs.** We define two structs, **Vertex** and **Graph**, to represent the vertices and the graph itself in our simple directed graph model for the network of interest.

Note that to align with Julia conventions, we use 1-based indexing. [1]

```
# export Vertex, Graph

struct Vertex
index::UInt32
in_neighbors::Vector{UInt32}
out_neighbors::Vector{UInt32}
```

```
7 end
8
9 struct Graph
10 num_vertices::UInt32
11 vertices::Vector{Vertex}
12 end
```

3.2. Input. We define three functions, read_graph, read_edge_list, and read_adjacency_list, to read and construct graphs from text files. We expose read_graph to the client with the option to specify the type of the input file and whether or not the input file uses 0-based indexing.

Edge list files follow the following format:

```
1 [num_nodes] [num_edges]
2 [index_from] [index_to] # repeats [num_edges] times
3 ... # in total
```

Adjacency list files follow the following format:

```
1 [num_nodes]
2 [index_to_1] [index_to_2] ... [index_to_m] # repeats [num_nodes] times
3 ... # in total
```

The code for read_graph, read_edge_list, and read_adjacency_list can be found in the Appendix.

- 3.3. PageRank. We divide the PageRank algorithm into three steps:
 - (1) Generating the transition matrix: pagerank_matrix.
 - (2) Running the transition process: pagerank_iteration, pagerank_epsilon.
 - (3) Returning the desired output: pagerank_print, pagerank.
- 3.3.1. Generating the transition matrix. The function pagerank_matrix generates a Markov matrix M that specifies the transition probabilities of the PageRank transition process.

We first compute the entries in M prior to damping, casing on whether the origin vertex is a "sink" (no outgoing neighbors), and then apply the damping at the end.

```
function pagerank_matrix(graph::Graph, damping::Float64)
1
     M = zeros(Float64, (graph.num_vertices, graph.num_vertices))
2
     for vertex in graph.vertices
3
       num_out_neighbors = length(vertex.out_neighbors)
4
       if num_out_neighbors == 0
5
         for index_to in 1:graph.num_vertices
6
           M[index_to, vertex.index] = 1 / (graph.num_vertices - 1)
7
8
         M[vertex.index, vertex.index] = 0
9
10
         for index_to in vertex.out_neighbors
11
           M[index_to, vertex.index] = 1 / num_out_neighbors
12
13
         end
       end
14
```

```
end
15
     map(x -> damping * x + (1 - damping) / graph.num_vertices, M)
16
17
   3.3.2. Running the transition process. The functions pagerank_iteration and
   pagerank_epsilon both generate an initial stochastic vector and then carry out the
   transition process using the transition matrix.
   pagerank_iteration runs the process for a given number of iterations.
   function pagerank_iteration(num_vertices::UInt32, M::Matrix{Float64},

→ num_iterations::UInt32)

     M_pwr = Base.power_by_squaring(M, num_iterations)
     M_pwr * (ones(Float64, num_vertices) / num_vertices)
   end
   pagerank_epsilon runs the process until the norm of the difference vector is smaller
   than a given threshold, or until \|\vec{v}_{k+1} - \vec{k}\| < \epsilon.
   function pagerank_epsilon(num_vertices::UInt32, M::Matrix{Float64},
        epsilon::Float64)
     prev = ones(Float64, num_vertices) / num_vertices
2
3
      curr = M * prev
     while norm(prev - curr) > epsilon
4
        prev, curr = curr, M * curr
5
      end
6
      curr
7
   end
   3.3.3. Returning the desired output. We expose two functions to the client: pagerank
   and pagerank_print.
   pagerank calculates the PageRank scores for the input graph, with the option to
   specify the damping factor and the transition mode.
   # export pagerank_print, pagerank
1
2
   function pagerank(graph::Graph;
3
        damping::Float64=0.85, modeparam::Tuple{String, Union{Int64, UInt32,
4

→ Float64}}=("iter", 10))
      if damping < 0 || damping > 1
5
        error("invalid damping")
6
7
     M = pagerank_matrix(graph, damping)
8
      if modeparam[1] == "iter"
9
        if !(isinteger(modeparam[2])) || modeparam[2] < 0</pre>
10
          error("invalid param")
11
12
        pagerank_iteration(graph.num_vertices, M, UInt32(modeparam[2]))
13
     elseif modeparam[1] == "epsi"
14
        if modeparam[2] <= 0</pre>
15
```

error("invalid param")

16

17

end

```
pagerank_epsilon(graph.num_vertices, M, Float64(modeparam[2]))
else
error("invalid mode")
end
end
```

pagerank_print pretty-prints the PageRank scores along with relevant information about the top vertices for the input graph and scores pg.

The code for pagerank_print can be found in the Appendix.

- 3.4. **HITS.** Similarly, we divide the HITS algorithm into three steps:
 - (1) Generating the transition matrix: hits_matrix.
 - (2) Running the transition process: hits_update, hits_iteration, hits_epsilon.
 - (3) Returning the desired output: hits_print, hits.
- 3.4.1. Generating the transition matrix. The transition matrices for the hits algorithm are simply the adjacency matrix and its transpose.

```
function hits_matrix(graph::Graph)
1
    A = zeros(Float64, (graph.num_vertices, graph.num_vertices))
2
    for vertex in graph.vertices
3
       for index_to in vertex.out_neighbors
4
         A[index_to, vertex.index] = 1
5
       end
6
    end
8
    Α
  end
```

3.4.2. Running the transition process. The function hits_update computes the normalized new Authority and Hub scores from the previous Authority and Hub scores and the two transition matrices

The functions hits_iteration and hits_epsilon both generate the initial Authority and Hub scores and then carry out the transition process using the update function.

hits_iteration runs the process for a given number of iterations.

hits_epsilon runs the process until the norms of both difference vectors are smaller than the given threshold, or until $\|\vec{a}_{k+1} - \vec{a}_k\| < \epsilon \land \|\vec{h}_{k+1} - \vec{h}_k\| < \epsilon$.

3.4.3. Returning the desired output. We expose two functions to the client: hits and hits_print

hits calculates the Authority and Hub scores for the input graph, with the option to specify the transition mode.

```
# export hits_print, hits
1
   function hits(graph::Graph;
3
       modeparam::Tuple{String, Union{Int64, UInt32, Float64}}=("iter", 10))
4
     A = hits_matrix(graph)
5
     H = copy(transpose(A))
6
     if modeparam[1] == "iter"
       if !(isinteger(modeparam[2])) || modeparam[2] < 0</pre>
8
         error("invalid param")
9
10
       hits_iteration(graph.num_vertices, A, H, UInt32(modeparam[2]))
11
     elseif modeparam[1] == "epsi"
12
       if modeparam[2] <= 0</pre>
13
          error("invalid param")
14
15
       hits_epsilon(graph.num_vertices, A, H, Float64(modeparam[2]))
16
17
       error("invalid mode")
18
     end
19
   end
20
```

hits_print pretty-prints the Authority and Hub scores along with relevant information about the top vertices for the input graph and scores a and h.

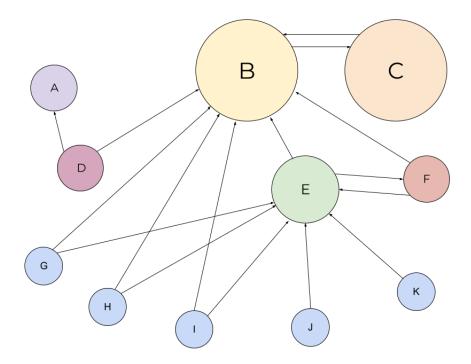

The code for hits_print can be found in the Appendix.

3.5. Output. We offer two ways of exporting the graph struct: generate_adjacency_matrix and generate_adjacency_list, which, well, generate the graph's adjacency matrix and adjacency list, respectively.

The code for generate_adjacency_matrix and generate_adjacency_list and be found in the Appendix.

4. Example

4.1. **The Wikipedia PageRank graph.** Shown below is a recreation of the medium-sized network with 11 websites displayed in the Wikipedia article on PageRank. [6][2] We will run both PageRank and HITS on this network.

4.2. PageRank.

4.2.1. *Expectations*. We expect websites B and C to have the highest PageRank scores because virtually every website links to it, either directly or through other websites such as E.

We also expect E to have a fairly high PageRank score because there are many websites linking to it.

Finally, we expect websites G, H, I, J, and K to have the lowest PageRank scores because they only have outgoing links.

4.2.2. Results. We run the following commands to apply PageRank on the network.

0.0811	5 l	6	3 # E
0.0392	4	1	2 # D
0.0392	6	1	2 # F
0.0303	1	1	0 # A
0.0162	7	0	2 # G
0.0162	8	0	2 # H
0.0162	9	0	2 # I
0.0162	10	0	1 # <i>J</i>
0.0162	11	0	1 # K

The first column lists the calculated PageRank score and the second lists the index of the website with that score. The "in" column displays the number of incoming links to the corresponding website. Similarly, the "out" column displays the number of outgoing edges from the corresponding website.

We see that, as expected, websites B and C have the highest PageRank scores by far, and E has the highest score of the remaining websites. Additionally, we see the websites G, H, I, J, and K share the same lowest PageRank score.

4.3. **HITS.**

4.3.1. Expectations. Recall the core concept of HITS: websites linked by websites with high Hub scores will have high Authority scores; websites linking to websites with high Authority scores will have high Hub scores.

With this in mind, we expect that websites B and E to have the highest Authority scores simply because they have the greatest number of websites linking to them.

However, since B does not link towards many other Authorities, its Hub score should be low. But E links to B, which has a high Authority score, so we expect the Hub score of E to be above average.

Similarly, the Hub score of C should be relatively high since it links to B, but the Authority score of C should be low because B does not have a high Hub score.

Finally, we expect the Authority scores of G, H, I, J, and K all to be very low because no websites link towards them. However, their Hub scores should be relatively high because they point to one or both of the highest Authority websites, namely B and E.

4.3.2. Results. We run the following commands to apply HITS on the network.

```
$ julia
julia > using ScottyRank
julia> G = read_graph("data/medium-el.txt", filetype = "el")
julia> a, h = hits(G, modeparam=("epsi", 0.01))
julia> hits_print(G, a, h, num_lines=11)
 -- vall | -- index | --
                                in | - -
                                           out |
--- authority ---
    0.7567
                     2 |
                                             1 | # B
                     5 I
                                 6 I
    0.6370
                                             3 \mid \# E
    0.0880 |
                     4 |
                                 1 |
                                             2 \mid \# D
                                 1 |
    0.0880 |
                     6 I
                                             2 \mid \# F
    0.0784 |
                     1 |
                                             0 | # A
                     3 |
                                 1 |
    0.0000
                                             1 | # C
                     7
                                 0 |
    0.0000
                                             2 \mid \# G
```

0.0000		8	0	2 # H			
0.0000		9	0	2 # I			
0.0000		10	0	1 # <i>J</i>			
0.0000		11	0	1 # K			
hub							
0.4259		6	1	2 # F			
0.4259		7	0	2 # <i>G</i>			
0.4259		8	0	2 # H			
0.4259		9	0	2 # I			
0.2836		5 l	6	3 # E			
0.2544		4	1	2 # D			
0.2306		3	1	1 # C			
0.1952		10	0	1 # <i>J</i>			
0.1952		11	0	1 # K			
0.0000		2	7	1 # B			
0.0000		1	1	0 # A			

Similar to pagerank_print, the first column of the first table lists the Authority score and the first column of the second table lists the Hub scores. The "in" column displays the number of incoming links to the corresponding website, and the "out" column displays the number of outgoing edges from the corresponding website.

As expected, the Authority scores of B and E are the highest, with C having a low Authority score. The vertices G, H, I, J, and K have Authority scores of 0 because no vertices point to them.

Furthermore, we see that the Hub scores are also calculated as predicted: the Hub score of F is the highest because F links towards both B and E, the two vertices with the highest authority scores. G, H, I also have very high Hub scores. However, J and K have lower Hub scores because they only link to one of the main Authorities.
